ABSTRACT

Hydrocephalus is enlargement of the ventricular system of the brain due to increased cerebrospinal fluid (CSF) volume and pressure. Congenital hydrocephalus is further classified as communicating and non-communicating depending on whether there is an obstruction to the flow of CSF or not.

Multiple causes have been identified in literature which has been summarized as an imbalance in the production and absorption of CSF. It can lead to cognitive impairment, cerebral palsy and visual field defects.

It is crucial to identify this condition prenatally as it can leave a debilitating impact on the fetus. Several modalities like ultrasound, computed tomography scans (CT) and magnetic resonance imaging (MRI) have been used to diagnose hydrocephalus. These can help reduce the disease burden and provide means for timely decisions.

Key words: Classification, Congenital Hydrocephalus, Diagnosis, Dilated Ventricles, Hydrocephalus, MRI, Prenatal, Ultrasound, Ventriculomegaly.

INTRODUCTION:

Hydrocephalus is the enlargement of the brain ventricular system due to an excess in the volume of cerebrospinal fluid (CSF). This excess of CSF maybe due to an overproduction or poor reabsorption, which results in raised intracranial pressure (ICP). Accumulation of CSF in the subarachnoid space is called external hydrocephalus. Multiple causes have been identified in literature which have been summarized as an imbalance in the production and absorption of CSF. Ventriculomegaly is a general term used for dilatation of ventricular system of the brain, irrespective of the cause.

Enlarged ventricles were identified by Hippocrates, Galen and Arabian physicians. It was then thought that this condition developed due to extracerebral collection of water. However, Thomas Willis in the 17th century clarified the concepts of the ventricular system and in the 18th century important anatomical structures like the Aqueduct of Sylvius, foramen of Monroe and foramen of Magendie were identified by Francis Sylvius, Alexander Monroe and Francois Magendie respectively. In 1886 Key and Retzeus documented the present-day concept of the flow of CSF. In 1913 Dandy and Blackfen were able to categorize and distinguish between communicating and non-communicating types of hydrocephalus.

The first sterile method for drainage of CSF by ventricular puncture was developed by Wernicke. Followed later by serial punctures, eventually ventriculo-subarachnoid-subgaleal shunt was developed in 1893 by Mikulicz. These procedures were polished over the years and centuries and eventually the year 1950 led to the evolution of modern-day shunts.

Cerebrospinal fluid is produced as an ultrafiltrate by the walls of the capillaries that are present in the choroid plexuses of the ventricles and is secreted by the action of Na+/K+ ATPase pump present in the walls of these capillaries. Recent data suggests that CSF plays an essential role in homeostasis and neuronal functions. Therefore, any disturbance in its flow can result in hydrocephalus and also dementia if this condition occurs in adults.

Walter Dandy developed experimental models to investigate the pathophysiology and treatment modalities for hydrocephalus in 1919. Based on these models the author was the first one to classify hydrocephalus as communicating and non-communicating.

Various researchers have classified hydrocephalus is different ways, Raimondi explained it as “water head” and hence included all the conditions which were responsible for increased volumes of intracranial water under the heading of hydrocephalus. The author, therefore, not just included the actual etiologies responsible for causing hydrocephalus but also linked it to various conditions which were responsible for this vascular edema.

Mori et al attempted to classify hydrocephalus based on the impact of treatment by studying 1450 patients in Japan. Oi and Di Rocco classified hydrocephalus in relation to the mechanism of obstruction to flow as primary, due to impedance to flow at a single point which included Arnold Chiari malformation and secondary hydrocephalus due to abnormal growth or hemorrhage.

In a review article by Shakeri et al., hydrocephalus was classified based on the pressure of CSF as (i) normal pressure...
hydrocephalus, (ii) high-pressure hydrocephalus (iii) hydrocephalus due to aqueduct stenosis with a frequency of 47%, 27% and 15% respectively. Liu J and Rekate classified hydrocephalus into communicating, due to insufficient absorption of CSF in the subarachnoid space and obstructive or Non-communicating hydrocephalus due to a blockade in the flow of CSF from the ventricles to subarachnoid space. Obstructive type is further sub-categorized into a congenital and an acquired type. Kalyvas et al. describes congenital hydrocephalus as occurring in infancy and does not have any associated cause. However, when there is a known specific causative factor such as an invasive tumorous mass or an injury or insult to the brain, acquired hydrocephalus may occur. Tully in 2014 attempted to classify hydrocephalus in a simplified way which has been summarized in table 1.

**Etiology:**

Hydrocephalus presents a wide and comprehensive etiology which ranges from idiopathic, to structural defects to chromosomal anomalies. This wide array of etiology has been summarized in table 2

MATHEMATICAL:

Data Base Used: Google scholar, PubMed, Pak Medinet and ERIC.

Articles filter criteria: the used keywords generated about 100 articles ranging over a period of 20 years, the search was then tweaked and words like prenatal, dilated ventricle and ventriculomegaly were added. This resulted in reducing the number to about 70 articles. Out of these the articles ranging from 2010-2018 were selected. The abstracts and methodology of these articles were first read and eventually after going through the complete article they were finally selected. However, 2 articles from the years 1995 and 1999 were also included because of their relevance to the topic under review.

**DISCUSSION:**

Incidence of congenital hydrocephalus was found to be maximum in Africa, followed by Latin America and lowest...

in USA, 316, 145 and 68 per 100,000 births. A prevalence of 0.34/1000 births was noted in Nigeria. 25 Male predilection was also observed by Dewan et al in their metanalysis study. 26, 27 Another author observed a relationship between male gender and the development of intracranial hemorrhage which is a risk factor for developing fetal hydrocephalus. 19 Age specific metanalysis study conducted by Isaac et al reported highest prevalence of 88/100,000 in pediatric age group followed by 11/100,000 in adults; and 175/ 100,000 in the elderly. 28 Munch et al in their study found a prevalence of 1.1/1000 live births out of which 75% had a positive family history. 29 A very high prevalence of 4 -12/ 10000 live births was observed in China as compared to European countries. The authors also observed a decline in congenital hydrocephalus because of widespread use of folic acid as part of antenatal care 30 Both studies found a higher prevalence of hydrocephalus in low income countries as compared to high income countries. 31, 32
Neurodevelopment is associated with mild to moderate cerebral palsy and visual field defects. It can lead to cognitive impairment, and untreated hydrocephalus depends on the severity of the hydrocephalus. It is most likely due to the course of disease rather than any errors of measurement.

The size of lateral ventricle should be measured as part of routine screening done in second trimester. Scans done in axial plane maximize the visualizations of frontal horns, septum pellucidum and the atria of the lateral ventricles. The part of lateral ventricle where the body, posterior horn and inferior horn meet is called the atrium of the lateral ventricle. Between 15 – 40 weeks of gestation the atrial width remains constant, that is < 10mm. Any increase in this measurement leads to ventriculomegaly which is classified by atrial width measured on ultrasound.

Several researchers have compared the results of prenatal ultrasound with MRI and postnatal autopsy results which have been summarized in table 3.

Hydrocephalus has been known to be associated with several other congenital anomalies which can be easily detected on prenatal ultrasound. Study conducted by Mahmoud et al in Sudan found stenosis of aqueduct of Sylvius to be most commonly and frequently associated anomalies (45%) followed by spina bifida (30%), Arnold Chiari malformation (20%) and Dandy Walker formation (5%). Ventricular septal defect, tetralogy of Fallot, diaphragmatic hernia, gastrochisis, hydronephrosis, urinary malformation are a few others which have been found to be associated with hydrocephalus.

Literature has identified shunt systems and endoscopic 3rd ventriculostomy as treatment modalities for hydrocephalus. Recurrence risk of hydrocephalus was found to be 55.6% in same sex twin, 6.6% in first degree relative, 2.1% in second degree relatives and 1.7% in third degree relatives. Impact of untreated hydrocephalus depends on the severity of the hydrocephalus. It can lead to cognitive impairment, cerebral palsy and visual field defects. Abnormal neurodevelopment is associated with mild to moderate hydrocephalus in 7 - 8% fetuses whereas with severe hydrocephalus in 58% fetuses.

**CONCLUSION:**

Ventriculomegaly or hydrocephalus can easily be identified in second trimester by transabdominal scans since it can lead to a multitude of neurodevelopmental disorders. Therefore, its early detection and screening is advised. CT scans can diagnose hydrocephalus and other anomalies as efficiently as ultrasound however it has risk of exposing the fetus and mother to radiations. Above all, this modality has high cost and lack of availability concerns attached to it in a developing nation such as ours. MRI is another significant tool to diagnose hydrocephalus, a coherence was identified in both modalities’ ultrasound and MRI, thereby enhancing the counselling and the pre and postnatal management of the patients.

Ultrasound remains as one of the cheapest, cost effective, easily accessible and most sensitive modalities which can prove to be of great value in detecting hydrocephalus. This in turn can allow the physicians and parents to make timely decisions regarding rehabilitation or termination of pregnancy thereby reducing the disease burden in the society.
